

Quantum RegeV Algorithm – Brief Resume

This document provides a short high-level summary based on the publicly referenced Quantum-RegeV-Cracker project and the broader literature around Oded Regev's quantum factoring ideas.

Overview

Quantum RegeV is presented as a quantum-assisted keyspace reduction and cryptanalytic research concept inspired by Regev-style quantum algorithms. The project combines classical search techniques with quantum-inspired estimation methods intended to reduce the effective search space before classical verification.

Main Concepts

- Quantum-assisted reduction of candidate key ranges.
- Iterative Phase Estimation (IPE) concepts.
- Regev-inspired lattice and period-finding ideas.
- Hybrid quantum/classical workflow.
- Focus on reducing computational effort rather than exhaustive enumeration.

Workflow (High Level)

1. Load target public-key data.
2. Estimate a reduced candidate region using quantum-inspired techniques.
3. Perform classical verification within the reduced search space.
4. Rank and validate surviving candidates.

Important Notes

The project should be viewed as experimental research software. Publicly available quantum computers are currently far from breaking real-world cryptographic systems at scale. Claims regarding practical recovery of large cryptographic private keys should be evaluated carefully and verified independently.

Reported 19-bit and 20-bit Results

According to the supplied illustration, the project author reports successful recovery of 19-bit key targets using approximately 16,384 shots/repetitions and reports partial success on selected 20-bit targets using a similar shot budget. These figures are project-reported results and should be independently verified under controlled testing conditions.

Illustrated Performance Claims

- 16-bit targets reportedly recovered with roughly 2,048 shots.
- 19-bit targets reportedly recovered with 16,384 shots.
- 20-bit targets reportedly recovered in some runs using 16,384 shots.
- Testing referenced IBM and IQM quantum hardware environments.

Keyspace Examples from the Illustration

19-bit example: approximately 262,144 candidate private keys.

20-bit example: approximately 524,288 candidate private keys.

The illustration presents these values as representative search ranges used in the demonstrations.

Don't tell me this was BruteForce i Upgraded >My RegeV_CODE But still didn't Uploaded it to Github So i Succeeded to Crack 16-bit with Only ~2048~ Shots/Repetitions.

(Use Qbraid-Platform & Used Both IBM/IQM.)
Now Succeeded to CRACK 19-bit ->16384 shots
Noisy Harder Also CRACKS 20-bit->16384 shots

• Bit length: 19
• Private key range:
HEX: 0x40000 to 0x7FFF
Bit range: 2^{18} to $2^{19} - 1$
The total number of possible private keys in that range is:
 $0x7FFF - 0x40000 + 1$
 $524287 - 262144 + 1 = 262144$
So the full keyspace size is:
 $2^{18} = 262,144$
 $2^{18} = 262144$
Answer: 262,144 possible private keys

Using Only 16384 Shots MY REGEV_CODE 99.90% CRACKS 19-bit .

For Bitcoin Puzzle #20, Harder To Crack but Cracked Most of Time 50 %
• HEX: 0x80000 to 0xFFFF
• Bit range: 2^{19} to $2^{20} - 1$
The total number of possible private keys in that range is:
 $0xFFFF - 0x80000 + 1$
 $1048575 - 524288 + 1 = 524288$
So the full keyspace size is:
 $2^{19} = 524,288$
Answer: 524,288 possible private keys

CRACKS 20-bit 50% Using Same Num_Shots 16384
